CNR Report No. 14-2
31 March 1975

ABSTRACT

The process of probing and measuring an HF channel for use in a stored channel simulator will prove useful only when the investigator has some knowledge of the channel conditions. Of particular interest are the channel Doppler characteristics and multipath structure. The operations required to provide a measure of these parameters include: (1) complex channel reconstruction; (2) pre-filtering to improve delay resolution; (3) channel snapshot generation; and (4) Doppler estimation. A set of flexible Fortran programs which meet these specifications are described in detail. Software verification is achieved by means of a program generated single sideband HF test channel. In addition, programming changes to the previously reported channel measurement and reproduction software are documented. These result in significant decreases in computation time.

SECTION 1

INTRODUCTION AND REPORT SUMMARY

The results of probing and measuring an HF channel can be employed, ostensibly, to test communications systems over actual channels without resorting to full field experiment. If tests are conducted with the results of many channel soundings, a comprehensive picture of total system performance may evolve. Critical to this evaluation, however, is an awareness of the characteristics of the measured channel. Specifically, channel definition by means of its multipath structure and Doppler width is important.

In Section 3 of this report, we describe a software system capable of reducing the data on a channel probing tape to a meaningful set of parameter values. These include delay power density, Doppler power density, rms multipath spread, rms Doppler spread, and mean Doppler shift. In addition, modifications to the channel measurement and reproduction software (Part 1 of this report), which result in less execution time, are described in Section 2.

Throughout this report, we frequently refer to a set of programs which are printed in Part 1 of this final report, dated 15 May 1974. Each of these programs can be easily distinguished since they appear in Appendix P of that report (Figures P.1 to P.22).

SECTION 2

CHANNEL MEASUREMENT AND CHANNEL PLAYBACK SOFTWARE MODIFICATIONS

In Part 1 of this final report (covering the period 15 October 1973 to 14 April 1974), we discussed in some detail the concept of a stored channel simulator capable of measuring and reproducing a linear time-variant HF channel over a finite bandwidth. To demonstrate the stored channel technique, a set of Fortran programs were written which covered four major simulator topics: 1) probing signal generation; 2) channel measurement; 3) channel playback; and 4) simulator verification by means of a deterministic time-varying test channel.

Although no specific fidelity criteria for channel reproduction was adopted, empirical evidence suggested that the deterioration resulting from all self-noise sources (dc crosstalk, harmonic cross-talk, computational inaccuracies) was more than 70 dB below the desired signal. Unfortunately, the programs took prohibitively long periods of time to process useful quantities of data (30 seconds to 1 minute). In the following sections we will briefly describe the modifications made to the channel measurement and channel playback software to achieve a significant reduction in execution time.

2.1 Channel Measurement Software

The program which performs the channel measurement function is entitled RECD11. It is identical in operation to the program REC2 as described in the first part of this report. However, REC2 requires approximately 40 hours of CPU time to process one minute of data - a real time expansion factor of 2400. In contrast, RECD11 will massage the same quantity of data in 3.5 hours - a real time expansion factor of 210. Although much of this improvement can be attributed to NRL's recently acquired PDP-11/45 floating point processor, a 50% time savings has been achieved through software changes.

A listing of RECD11 appears in Figure A.1. Observe that, at the beginning of execution, the user is asked to input the name of the output data file he wishes to create on magnetic tape. Each record of this file will contain one measured snapshot (of length 255 samples) of the channel impulse response. As an example, suppose the desired name is CHANL.DAT. The user simply types CHANL since the program always appends .DAT. The only other additional input required by the program is the number of snapshots to be processed.

Two subroutines are called by RECD11 which were not accessed by REC2. Subroutine STASH (Figure A.2) is called with the following syntax:

```
CALL STASH(IJKM,ICSDR)
```

STASH simply places the value of IJKM in the address specified by the variable ICSDR. In this program, ICSDR = "177570 which corresponds to the address of the display register on the PDP-11/45, and IJKM contains the number of snapshots which have been written on magnetic tape. This gives the user an indication of the amount of data processed without having to resort to the use of a device such as the keyboard (whose device driver alone is 600 words).

Assembly language subroutine LOOP (Figure A.4) only replaces seven lines of code in REC2. However, since much of the program's time is spent executing those lines, their replacement by LOOP decreased execution time by a factor of 2. It achieves its speed by making very efficient use of the floating point processor.

TESTD.DAT is the name of the input data file for RECD11. Each record of the file must contain 510 samples of channel data (510 samples have a time duration equivalent to two times the inverse of the snapshot rate). However, data derived from NRL channel probing experiments is recorded in 1000-word 12-bit packed blocks on magnetic tape by MTIN (Figure A.5). In order to be used, this data must be

reformatted so that it becomes compatible with the requirements of RECD11. FORM1A (Figure A.6) accomplishes this objective. In addition, it positions the data before executing by skipping a user specified number of files and 1000-word records. Subsequently, FORM1A performs the following functions:

- (1) Reads channel data in 1000-word 12-bit packed blocks from magnetic tape using call to the NRL supplied input routine MTIN. The data is left-justified in a 1000-word integer array IAR.
- (2) The data in each word of IAR is shifted right by four bits for normalization. Since the data is recorded in offset binary, "4000 is subtracted from each word.
- (3) IAR is then converted to floating point and appropriately placed in array X (of dimension greater than 1000).
- (4) X is reformatted into 510 word blocks and written on magnetic tape under the file name TESTD.DAT.

FORM1A replaces FORM1 which appeared in Figure P.5 of the first report. As its predecessor, FORM1A used modulus arithmetic and treats the data storage vector X as though it were circular. In this way, no internal data moves need be performed - allowing the programs to execute more quickly than might normally be expected. One additional feature has been included which forces FORM1A to print the magnetic tape status word on device 6 should an error occur during a read.

Function LSH (Figure A.3) is used by FORM1A to perform shifting operations. Its call must have the syntax LSH(IWORD,J), where IWORD is an integer variable to be shifted left by J bits. As an example, for J = -4, the contents of IWORD are shifted right by four bits.

2.2 Channel Playback Software

The task of decreasing execution time for the channel playback software requires a more sophisticated approach than that required for the channel measurement software. The approaches necessarily differ because the sources of wasted time in the two sets of software differ. In the channel measurement case, certain Fortran statements were consuming huge amounts of CPU time; in the channel playback situation, large amounts of time are spent preparing and transferring data from program storage to intermediate data storage on disk files. This was originally necessitated by the insufficient core storage available (20K words) on the NRL PDP-11/45.

The original playback program PLAY2 is listed in Figure P.11 of the first report. It suffers from the extraordinary complexity rendered by the use of five data files. This is abundantly obvious when PLAY2 is compared to a completely equivalent program, PLAY, designed to run on the PDP-10. PLAY is listed in Figure P.22. It seems clear that the only way to effectively speed program execution is to allow most intermediate data to remain in core. To this end, we have adopted an overlay program structure.

In order to eschew any proclivity toward prolixity, we will not discuss the numerous revisions necessary before working software was completed. Merely observe that overlaying by itself is not sufficient. More surreptitious means for saving storage are required.

PLAY2 defines the files to be used by calls to the Fortran subroutine SETFIL. SETFIL is used instead of ASSIGN because random access files are needed. Each call to SETFIL requires about 20 words, while SETFIL itself is approximately 250 words long. Thus, just setting the five files in PLAY2 requires 350 words of PDP-11/45 core. In addition, we determined than only three devices were required in the overlaid program: 1) PLAYD.DAT is the file that contains data

to be played through the channel; 2) RECDT.DAT contains the transform of the recorded channel snapshots; and 3) PROCD.DAT contains the processed data. In addition, the device table on the PDP-11/45 requires 19 words of storage for each logical unit number independent of whether it is used. Since there is nominally provision for eight logical units, we could conceivably remove five logical unit numbers for the overlayed programs and form what we might term a minimum device table.

Taking this discussion to its logical conclusion, we can place the file names directly in the minimum device table and thereby eliminate the need for program SETFIL, five calls to SETFIL, five unnecessary logical unit numbers, and 435 words. A listing for the device table MINDEV, which accomplishes this objective, appears in A.7. It assigns PLAYD.DAT to logical unit number 1 on disk unit 0, and RECDT.DAT to logical unit number 2 on magnetic tape unit 0. The third file, PROCD.DAT, is assigned to logical unit number 3 and device unit number 1 on either disk or magnetic tape. The device chosen depends on the output of a conditional assembly. The user required alteration can be gleaned from the program listings.

Another source of wasted core involves the Fortran I/O package and its interface with the Fortran error handling routines. We decided to put all the device reads and writes in the smallest overlay segment and to eliminate any I/O from the root segment and the remaining overlay segments. Unfortunately, the Fortran error processor requires a good deal of the Fortran I/O package and, of course, it necessarily must appear in the root segment. Program ERRF (Figure A.8) allows us to circumvent this problem by replacing the Fortran entry points ERR, ERRA, ERRB, ERRC, ERRF with a set of entry points in ERRF. In case an error occurs, the program puts a message of the form F030 ABC XYZ on the keyboard. In this case, ABC = error class, XYZ = error number (both in octal). It writes on

the keyboard without requiring a buffer allocation by taking advantage of a resident monitor program. In addition, ERFF has another entry point ERR000 which can be employed for additional error indications. ERFF saves over 1000 words of storage.

Figure 2.1 depicts the overlay structure used by the program. The root segment PLAY11 (Figure A.9) has three branches. Branch B contains subroutine LAGINT in file LAG1. LAGINT appears in Figure P.8 of the first report. Branch C contains subroutines SUB1 (Figure A.10), ZWRITE (Figure A.11), and SUB2 (Figure A.12). Branch D contains subroutine FFTOVR (Figure A.13) which, in turn, calls two overlay segments. Branch E contains subroutine FFT (Figure A.14) and Branch F contains subroutine REALTR (Figure A.15). A Fortran equivalent of assembly language subroutine SUB2 appears in Figure A.16. All of these programs must be linked together with the aid of the overlay description file PLAY11.ODL listed in Figure A.17.

As a result of the programming changes, the channel playback software now requires that the data to be played through the channel be formatted in 255-word records instead of the 765-word records required in the old software. However, this requires only a change in a parameter in program FORM2 (Figure P.12).

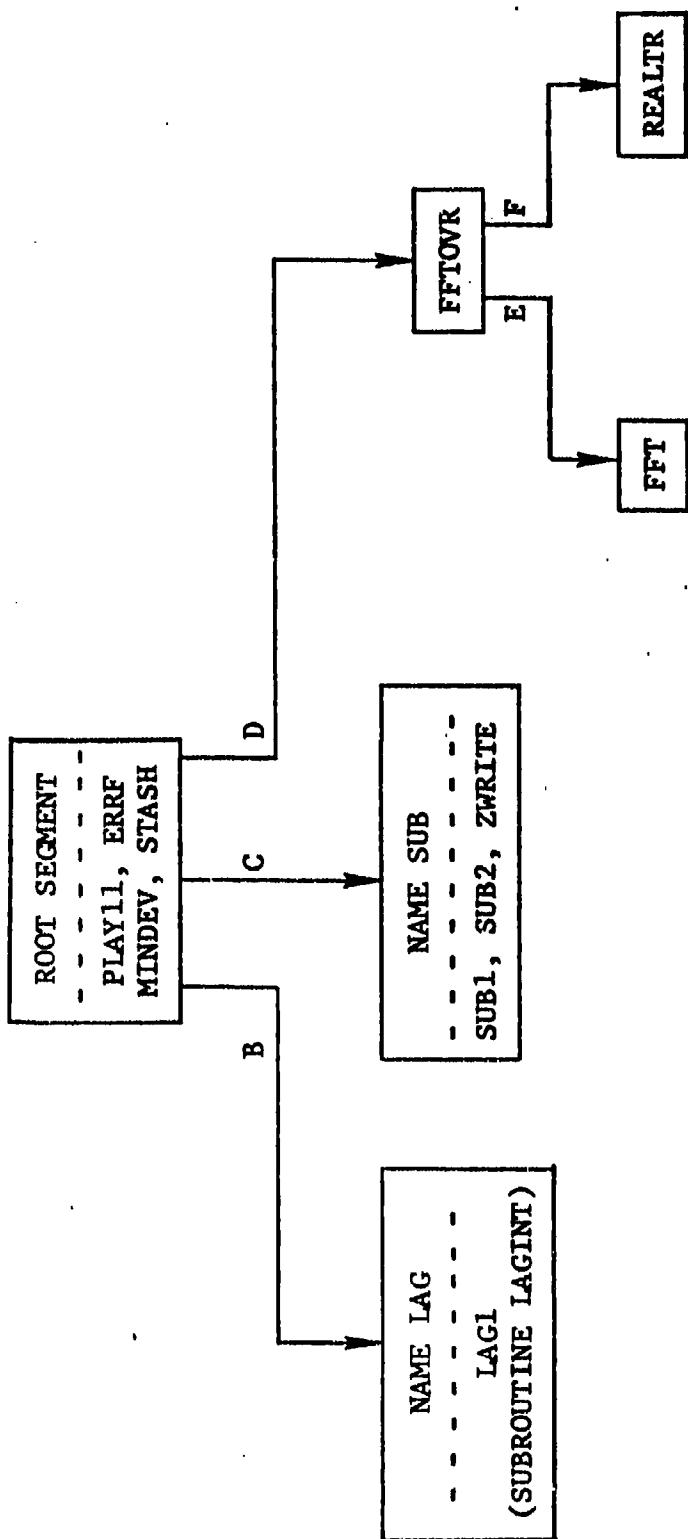

Figure 2.1 Overlay Structure for PLAY11.

SECTION 3

DELAY SPREAD AND DOPPLER WIDTH CHARACTERIZATION OF CHANNEL MEASUREMENT RECORDINGS

During the course of this program, two separate probings of the HF channel have resulted in several magnetic tapes of channel soundings. It is difficult to use these tapes for other experimental work (such as modem development) without some knowledge of the character of the channel they represent. Exclusive of additive noise interference, two commonly used characterization parameters are multipath spread and Doppler width. We shall discuss a set of Fortran programs which are capable of extracting some measure of these parameters from the channel probing tapes.

3.1 System Background

Part 1 of this report contains a discussion of the constraints placed on the channel measurement process by both the details of the NRL single-sideband (SSB) transceiver and the specifics of the probing signal (Sections 2 and 5). However, we can summarize their combined effect on an ideally white probing of the channel by the spectral shape presented in Figure 3.1. Although the long flat regions of the spectrum allow channel characterization over a broad bandwidth, the fast spectral rolloff at the band edges adds several milliseconds of multipath spread to the multipath actually contributed by the channel.

For the purposes of the channel measurement and playback recordings previously described, it is important to maintain a broadband "total" channel characterization in order that the data used during playback be a fair example of the information transmission effects to be encountered. We are interested in categorizing the transmission medium; therefore, we must reduce as much as possible the effects of the transceiver filters and the spectral weighting of

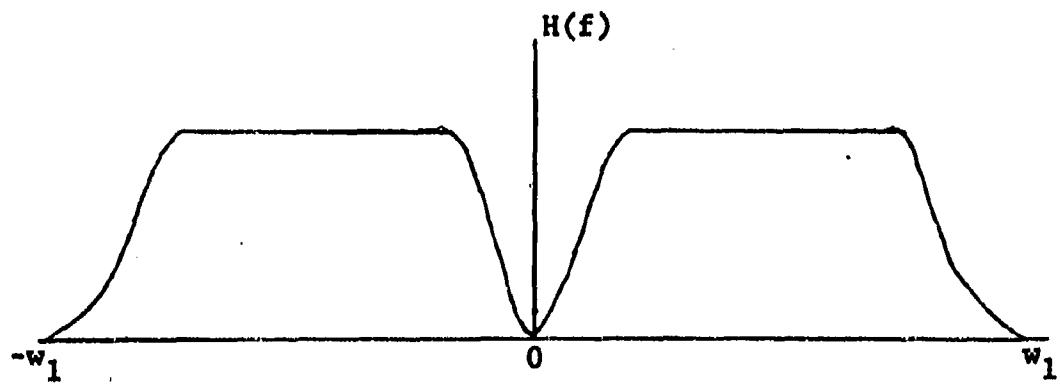

Figure 3.1 Combined Spectral Shape of NRL Transceiver
and Probing Signal

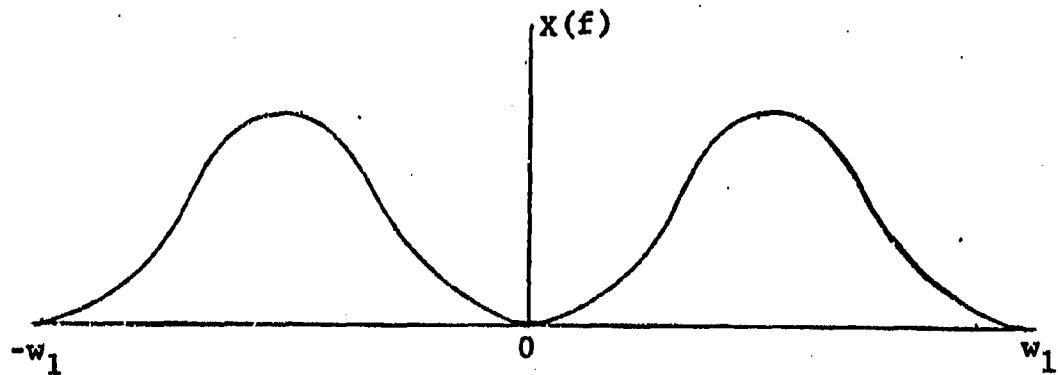

Figure 3.2 Spectral Shape Used to Improve Delay Resolution

the probe signal. One spectral shape which accomplishes this objective and which can be applied to a baseband signal, $z(t)$, appears in Figure 3.2. It is straightforward to show that the impulse response of this filter is

$$x_1(t) = \frac{\sin \pi w_1 t \cos \pi w_1 t}{\pi t (1 - w_1^2 t^2)} \quad (3.1)$$

which, when sampled at a $2w_1$ rate, becomes

$$\frac{x_1\left(\frac{k}{2w_1}\right)}{w_1} = \begin{cases} 1 & ; k = 0 \\ -\frac{1}{2} & ; k = \pm 2 \\ 0 & ; \text{elsewhere} \end{cases} \quad (3.2)$$

The only additional processing required before the channel measurement procedure can begin involves reconstruction of the complex SSB demodulated output, $x(t)$, where

$$z(t) = \operatorname{Re} \left[x(t) e^{j(w_{\text{off}} t + \theta)} \right] \quad (3.3)$$

where θ and w_{off} are, respectively, phase and frequency offsets between the receiver and transmitter filters. Assuming that w_{off} is small compared to any dead zone around dc in Figures 3.1 and 3.2, then we can say that

$$z(t) + j \hat{z}(t) = x(t) e^{j(w_{\text{off}} t + \theta)} \quad (3.4)$$

where $\hat{z}(t)$ is the Hilbert transform of $z(t)$.

Of course, we could have formed the complex signal $z(t) + j \hat{z}(t)$ before weighting by the SSB equivalent of the spectrum in Figure 3.2. However, software considerations were preeminent in the rejection of this procedure.

3.2 Software

A block diagram of the required software is given in Figure 3.3. Observe that we have decreased the order of the interpolator used during channel measurement from a fourth-order Lagrange to a second-order Lagrange. This was necessitated by the interplay between the higher core requirements for complex processing and the finite amount of core available. However, since the requirements for channel characterization are less stringent than those for channel reproduction, the interpolator order reduction is not significant. For example, in Part 1 of this report we noted that 0.1 dB Doppler attenuation occurs at ± 5.65 Hz for a fourth-order interpolator and at ± 2.4 Hz for a second-order interpolator. At 5.65 Hz, a second-order interpolator renders only 0.6-dB attenuation — an acceptable quantity for channel characterization.

The Hilbert transformer depicted in Figure 3.3 can be implemented in a great many ways. We chose to use a finite impulse response (FIR) linear phase digital filter. Toward this end, we employed a program written by McClellan, Parks, and Rabiner for optimum FIR filters [3.1]. The design was restricted by three criteria: 1) that the frequency response of the filter appear white with respect to the transceiver filter-probing signal spectral combination of Figure 3.1; 2) that passband ripple magnitude be less than 1%; and 3) that the order of the filter (the duration of its impulse response) be odd. (Since for N odd every other sample is zero, the last requirement is important to minimize computation.) A FIR filter of length 43 satisfies these criteria.

The Hilbert transformer is, of course, odd symmetric and unrealizable. As a result of its finite impulse response, the filter can be made realizable by inserting a delay of 21 samples in the untransformed path. This is indicated in Figure 3.3. The odd symmetry is computationally important since it allows the

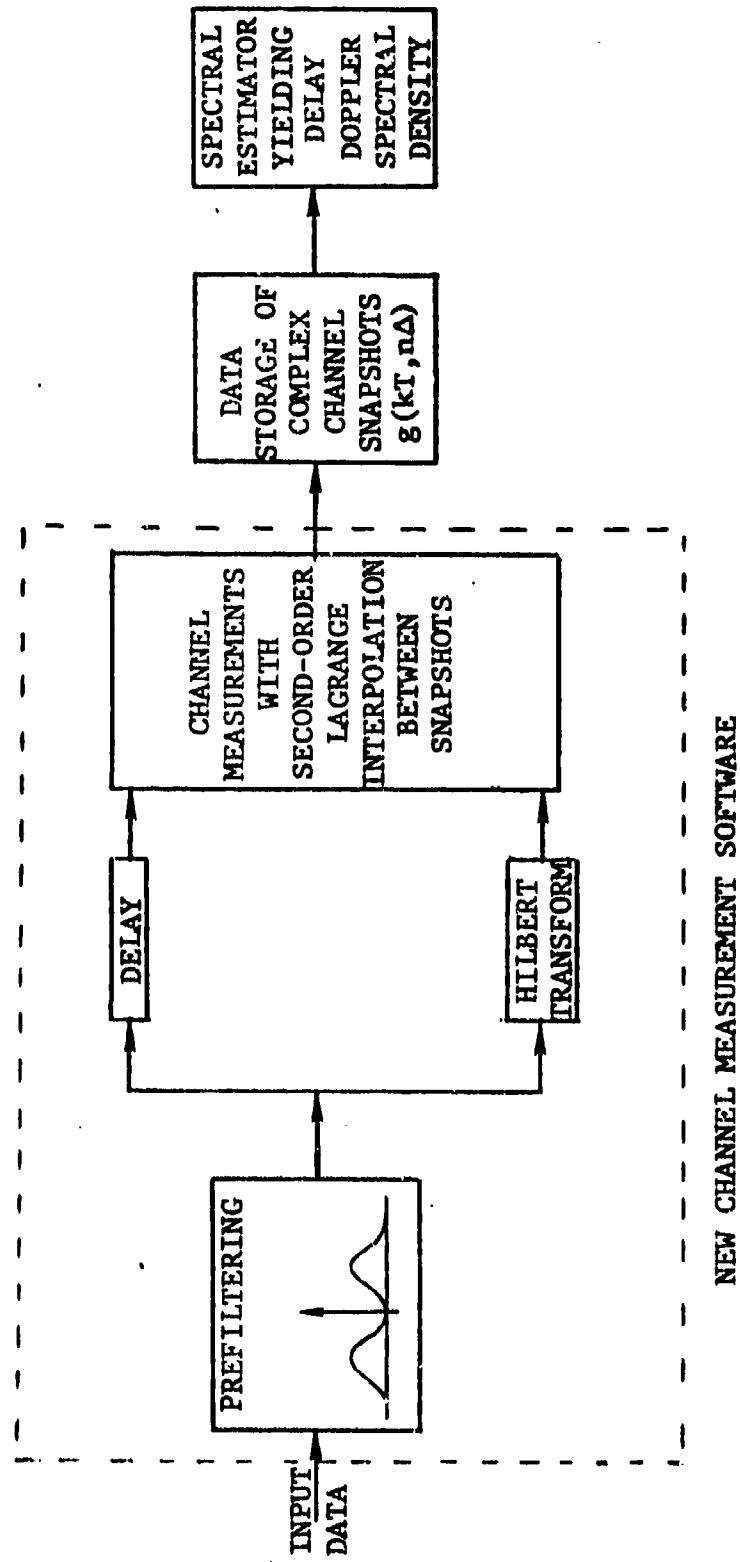

Figure 3.3 Software Block Diagram

programmer to replace two multiplies by a multiply and a subtract. Thus, the 43 sample impulse response requires only 11 multiplications and 11 subtractions.

Figure 3.4 is a block diagram of a technique for measuring the spectral characteristics of a Hilbert transformer. The amplitude response of the filter on linear and log scales appears in Figures 3.5 and 3.6, respectively. Observe the equiripple response of this optimum filter in both the passband and stopband.

We chose to combine (1) prefiltering to improve delay resolution, (2) complex channel reproduction, and (3) the channel measurement procedure into one program named RECSCF (A.18). The word RECSCF is a slightly misnamed acronym for REcord SCattering Function. (A scattering function is not actually calculated - only an estimate of its transform along the Doppler dimension.)

Program RECSCF requires four files: 1) a random access file for temporary data storage STOR1.DAT; 2) a file LAGR.DAT containing second-order Lagrange interpolator coefficients [created by SETLAG (A.19)]; 3) a file TESTD.DAT formatted in records of 510 words containing the data to undergo the channel measurement process; and 4) a magnetic tape output file whose name is inputted by the user. In addition, the user must specify the number of snapshots to be processed by the RECSCF. If the number of snapshots specified is greater than the length of the input data file, the last record read is processed, a normal termination ensues, and the user is informed that an end of file has been encountered. The program performs one subtle maneuver to save execution time by subtracting "200 from the first word of a floating point number instead of dividing by 2.

When the program terminates, a summary of the total power at each tap is written on the line printer. This information is important to the user who must subsequently determine which taps are to be examined for Doppler spread characteristics.

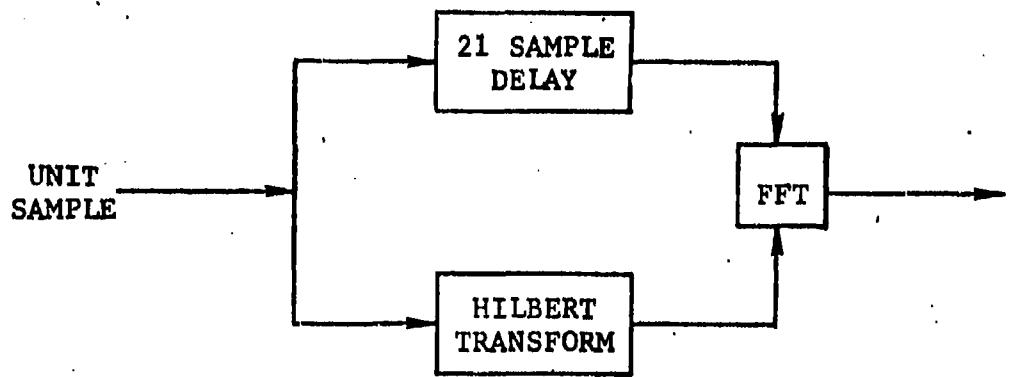

Figure 3.4 Hilbert Transformer Test

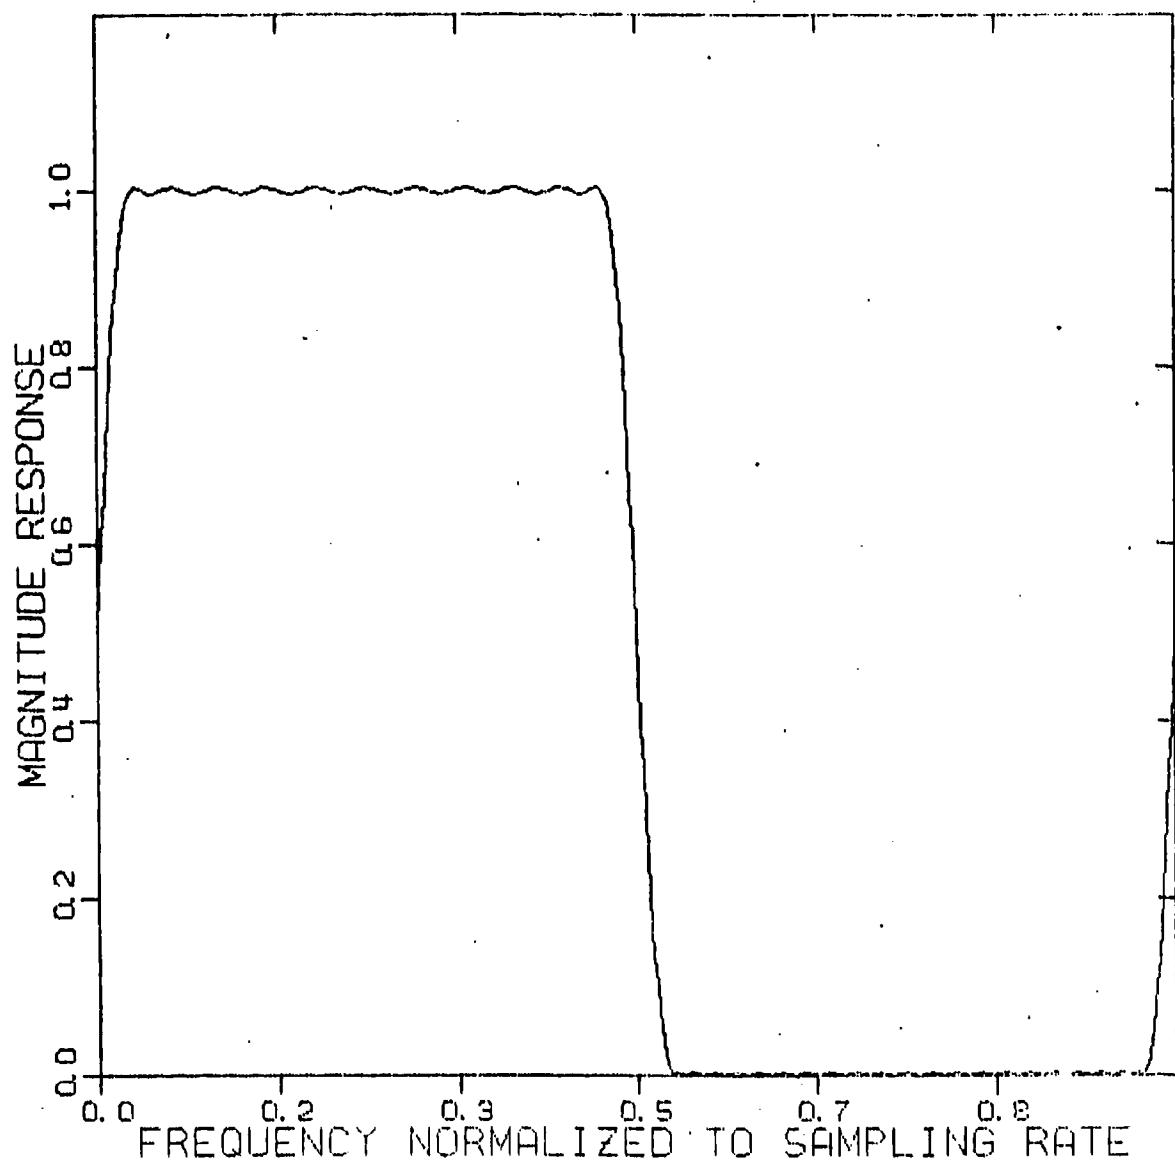

Figure 3.5 Spectral Response of Single Sideband Extractor
(Linear Scale)

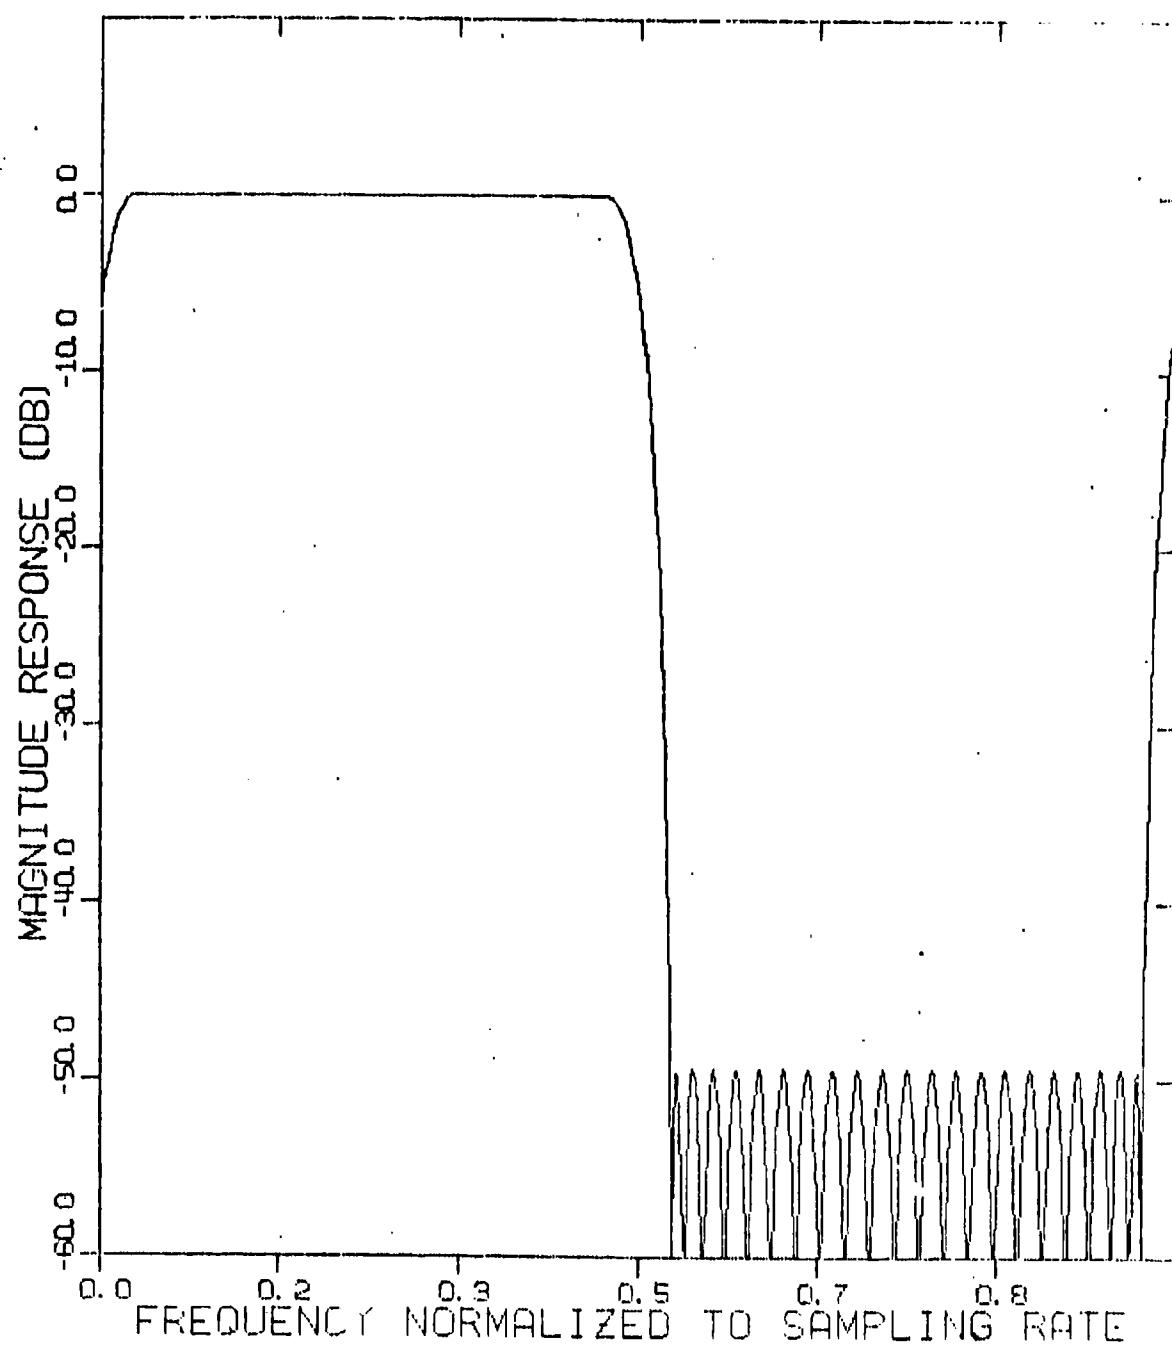

Figure 3.6 Spectral Response of Single Sideband Extractor
(Log Scale)

Define $g(kT, n\Delta)$ to be one complex snapshot of the channel impulse response, where $\frac{1}{T}$ is the snapshot rate, and $\frac{1}{\Delta}$ is the sampling rate ($2w_1$ in Figure 3.2). As discussed in Part 1 of this report, each tap in a tap delay line channel model is separated by Δ seconds. During playback, each tap coefficient is updated every T seconds. As an indication of delay spread, we are interested in the power in each tap averaged over the number of snapshots processed. Normally, only a few taps will contain significant energy. For example, a 1-ms multipath spread at a 9-kHz sampling rate would involve only 9 taps. However, coupled with a bandwidth reduction filter length of five samples (3.2), this yields 13 taps which contain some meaningful information. The starting and end indices of the taps with significant energy can be ascertained from the RECSCF line printer output. It is on this set of taps that we would like to perform spectral estimation in the Doppler dimension.

Techniques for calculating power spectra are straightforward and well cataloged. The one which we selected for this software system falls under the general topic of linearly modified spectral estimates [3.3]. This method is distinguished by the subdivision of data into windowed segments prior to transforming. A succinct description follows of the steps involved in producing that which might be termed in the ideal case "consummate spectra".

- (1) Choose the length of the FFT to be used according to the Doppler resolution required. For example, frequency resolution of an FFT = $\frac{1}{NT}$ Hz, where N is the number of samples in the FFT and T is the distance between time samples of the FFT data base. In this case, $\frac{1}{T}$ (35.294 Hz) corresponds to the inverse of the snapshot rate. For $N = 64$, frequency resolution is approximately 0.551 Hz, which for many applications is adequate. Of course, we could increase the length

of the FFT to attain better resolution if we are willing to increase the variance of the spectral estimate [3.4].

- (2) Choose a time window for weighting the data. There are obviously many from which to choose. In addition, once the weights have been established, all are equally easy to apply. The one we have chosen to use is termed an optimal window by A. Eberhard [3.2]. This window maximizes the ratio of the energy in the mainlobe of the window spectrum to the total energy in the spectrum.
- (3) Apply overlapping windows to the data base, as indicated in Figure 3.7. This method minimizes the loss in potential spectral information that nonequal weighting of the data base renders. Ideally, the sum of the values of all windows in the data base at each element in the data base should be unity [3.5].
- (4) Weight each overlapping segment in the data base with the window coefficients, take a FFT, find the magnitude square, and average over all segments. For the parameter values listed above, there are approximately 45 periodograms averaged for each tap, given one minute of input data.

A program for computing Doppler spectra at each tap position, DDSPEC, is listed in Figure A.20. The user must input the name of the magnetic tape data file which contains the recorded snapshots of the channel impulse response. He must also enter the indices of the left and right tap boundaries surrounding the taps to be processed. For example, if the user wants taps 245-255 and 1-6 processed (17 taps), he merely enters 245,6,. The maximum circular separation of the tap boundaries entered must be less than or equal

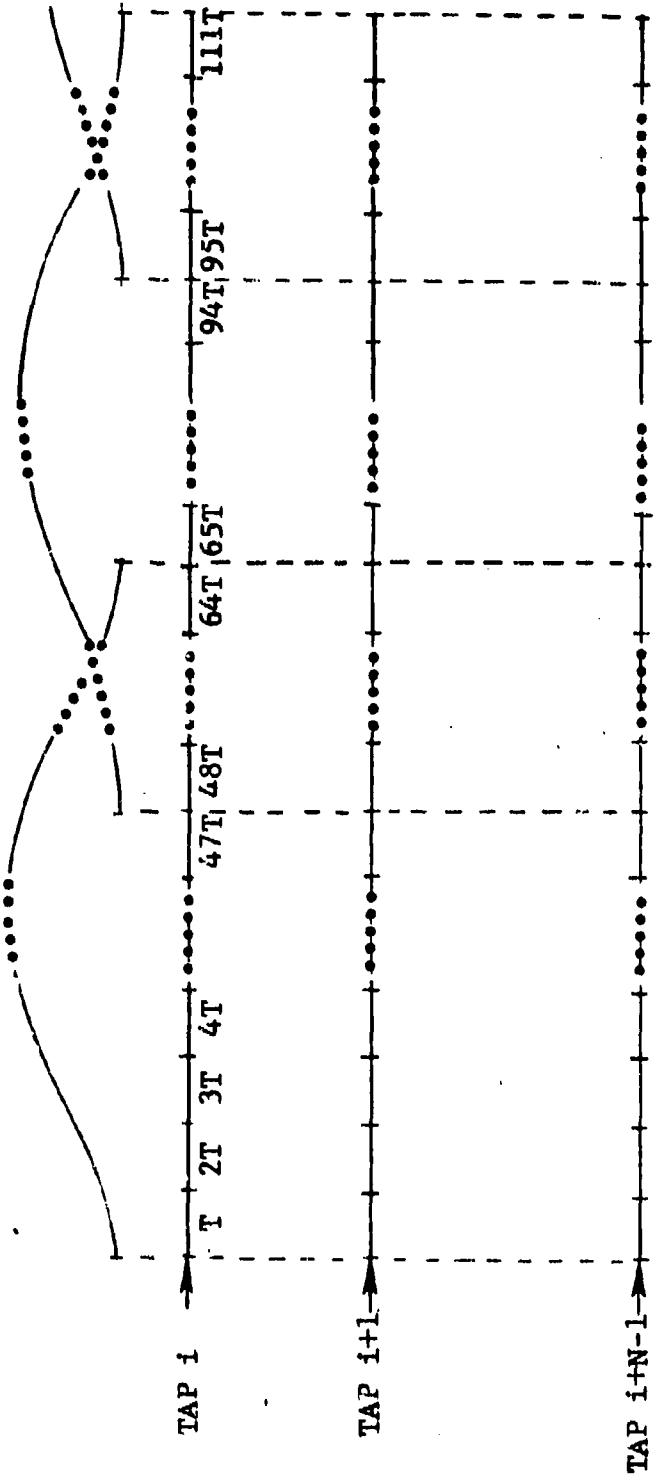

Figure 3.7 Window Overlap During Doppler Estimation Process

to 84. In the example just given, the circular tap separation is 16. The program creates a random access output data file DELDOP.DAT which contains the final spectral estimates at each tap position specified. A summary of this file is written on the line printer just prior to program termination.

Another program, DDREAD (Figure A.21), massages DELDOP.DAT and prints its contents in a format which is conducive to visual extraction of gross physical details of the delay Doppler surface. Up to 14 taps can be presented in this way at any one time. An example of this format will be given in the next section.

For the user who would rather see a statistical summary of the information collected, program DDSTAT (Figure A.22) is available. It reports the following information via the line printer:

1) marginal delay power distribution for the taps examined and the time in seconds by which each tap is separated; 2) marginal Doppler power distribution over a specified range of frequencies; 3) mean delay with respect to the first tap examined; 4) rms delay; 5) mean Doppler; 6) rms Doppler spread; 7) the taps at which delay peaks occur and time differences in seconds between peaks; and frequencies in Hz at which Doppler peaks occur; 9) Doppler statistics at each tap delay; and 10) graphs of marginal delay power and marginal Doppler power. An example is given in Section 3.4.

3.3 Software Verification (Basic Programs)

For the purposes of software verification, it is necessary to create a complex SSB HF channel with typical multipath and Doppler characteristics. The approach we shall take is summarized in Figure 3.8. This system is designed to emulate probing with a PN sequence - the result of which is a set of frequency samples of the HF channel where the intersample space in Hz is equal to the inverse of the length in seconds on one period of the probing signal. (More details of the probing process are presented in Part 1, Section 5,

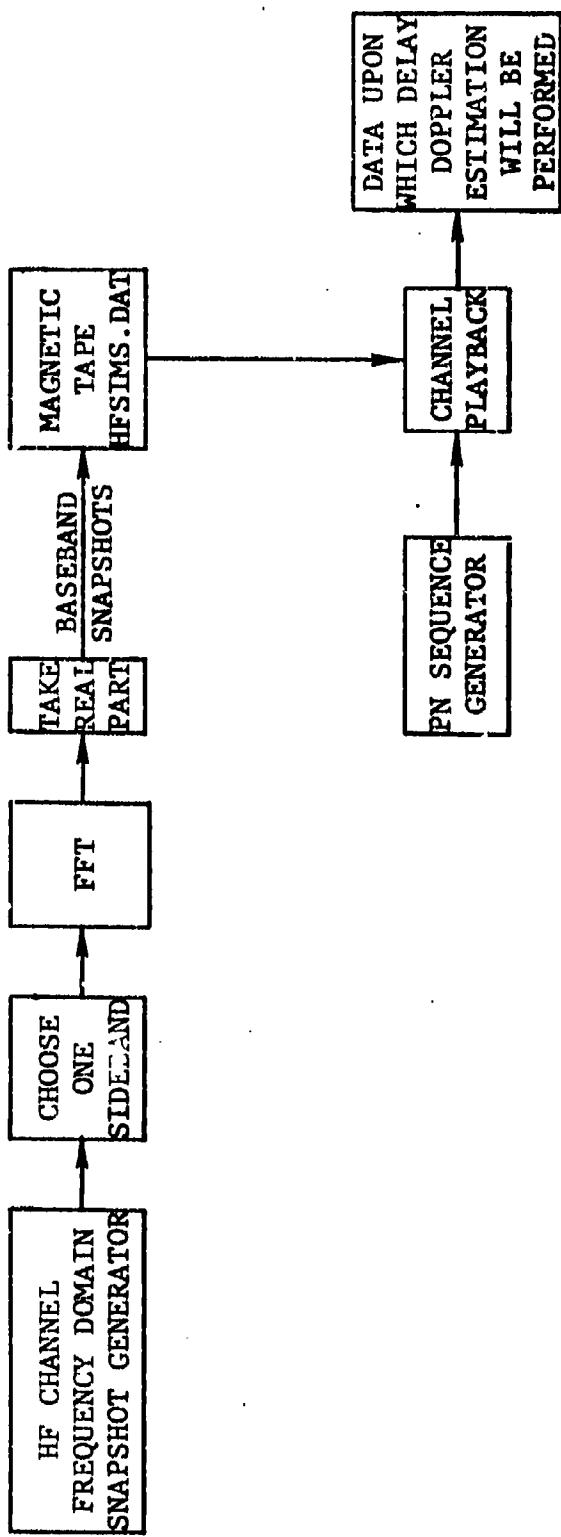

Figure 3-8 Test Channel Generation

of this report.) An equivalent software approach involves weighting the line spectrum of a periodically repeated PN sequence by a simulated complex HF channel.

Ideally, the response of one path of the HF channel to a sinusoidal input of the form

$$x(t) = \sqrt{2P} \sin(\omega t + \theta) \quad (3.5)$$

is

$$y(t) = \sqrt{2P} r \cos(\omega t + \theta + \varphi) \quad (3.6)$$

where r is the time-varying Rayleigh-distributed amplitude of the path and φ is the phase resulting from Doppler, time delay, etc. In general, a complex noise process should be added to $y(t)$; however, for the purposes of test channel generation, we shall only consider the noiseless case.

Similarly, the received signal over a multipath channel at any tone is

$$y(t) = \sqrt{2P} \sum_{j=1}^N r_j \cos(\omega t + \theta + \varphi_j) \quad (3.7)$$

where the r_j are independent Rayleigh-distributed variables and N is the number of paths. For normalization purposes, we will constrain the sum over the power in the j^{th} path (P_j) to be unity:

$$\sum_{j=1}^N P_j = 1 ; E[r_j^2] = P_j \quad (3.8)$$

For an array of M tones

$$y(t) = \sum_{i=1}^M \sum_{j=1}^N \sqrt{2P} r_j \cos(w_i t + \theta_i + \phi_{ij}) \quad (3.9)$$

This model assumes that r_j is constant over all frequencies of interest while ϕ_{ij} is frequency-dependent. Both r_j and the Doppler-dependent portion of ϕ_{ij} can be obtained from a set of filtered complex Gaussian variables. In the program to be described, filtering is accomplished with a two-pole filter whose passband shape approximates typical Doppler rolloff characteristics.

A program, HFSIMS, which creates a SSB HF channel by frequency weighting a set of tones according to the desired multipath and Doppler characteristics is listed in A.23. The output magnetic tape data file, HFSIMS.DAT, will contain transforms of the baseband snapshots. Inputs to HFSIMS include: 1) the number of snapshots to be written on magnetic tape; 2) the number of frequency samples in the sideband of interest (by default, the program chooses the upper sideband); 3) the frequency separation between tones; 4) the snapshot rate (because of the details of the probing process, items 3 and 4 must be equal); 5) the number of paths in the channel model (non-impulsive path delay densities are not computationally feasible since any simulation using that model would require huge amounts of CPU time); 6) the Doppler bandwidth of each path (Hz); 7) the power of each path in dB (for normalized results, the total power in the paths should be unity); 8) the Doppler offset of each path (Hz); and 9), the relative delay (seconds) of each path (the first path should have a relative delay of 0).

Armed with synthetic snapshots of an HF channel, we are ready to simulate probing the channel with a periodically repeated PN sequence. This situation is identical to one encountered in Part 1 of this report in which it was necessary to play data through recorded snapshots of the channel. Program PLAY11 (A.9) accomplished this objective. It seems reasonable then to adopt PLAY11 for "playing back" the PN probing signal through the synthetic snapshots.

One simplification is in order. PLAY11 is capable of handling large bandwidth Doppler spreads or large Doppler shifts without imparting significant passband deterioration (Section 2 and 3 of Part 1). This is a result of using a fourth-order Lagrange interpolator for zeroing Doppler images at multiples of the snapshot rate. Since we are only testing the software, it is not necessary for these initial experiments to use relatively large Doppers. As a result, it will prove computationally expedient to use only a second-order interpolator while limiting maximum Doppler shifts to around 3 Hz. PLYSCF incorporates all these features into one program.

PLYSCF assigns four different data files during the course of its execution. File LAGR.DAT is created by program SETLAG (Figure A.19). File PNSEQT.DAT contains a 768 point real transform of one period of a PN sequence of length 255. Program SETPNS (Figure A.25) creates this file while employing the use of an FFT program specifically modified to perform a 384 point complex transform [FFT 384 (Figure A.26)]. File HFSIMS.DAT contains the transformed channel snapshots generated by HFSIMS. The last file, TESTD.DAT contains the result of playing a PN sequence through the synthetic channel. Should an end of file occur in HFSIMS.DAT, the program will terminate normally after printing the record number being processed when the EOF occurred. PLYSCF, like most of the main programs

previously described, puts a numerical indication of the record being processed on the display register.

An overlay program, PLYOVR (Figure A.27), is functionally equivalent to PLYSCF. It has the capability, however, of being able to incorporate any order interpolator by changing the value of the parameter IQ to reflect the order desired. Some obvious changes must also be made in array dimensioning. The user can also save an additional 400 words by incorporating a variation of the minimum device table program, MINDEV. The overlay segments, SUB1, FFTOVR, and SUB2 are listed in Figures A.28, A.29, and A.30, respectively. PLYOVR.ODL, which contains the necessary overlay descriptor language, appears in Figure A.31.

PLYOVR uses both synchronous and asynchronous manual load operations, as specified by the PDP-11/45 linker manual. (It should be observed that the bit used as a synchronous-asynchronous switch in CALL LOAD is reversed in all the documentation.) Manual load saves both time and memory when compared to the performance of the PDP-11/45 autoload feature. PLYOVR, using a second-order interpolator, executes quite rapidly. Approximately two seconds of computation per snapshot are required - corresponding to a real-time expansion factor of 70.

3.4 Test Examples

To establish program credibility, we have devised test examples which will exercise many of the software features. A summary of the programs required in the order of their execution appears in Table 3-1. As previously discussed, SETPNS and SETLAG create data files necessary for the synthetic test channel. The program which determines the characteristics of that channel is HFSIMS. Following the stated guidelines, we chose to keep the maximum excursion of significant Doppler energy to 3 Hz. Also, to insure that Doppler estimation would be performed over many Doppler cycles

TABLE 3-1
SUMMARY OF PROGRAMS REQUIRED FOR TEST EXAMPLE

Program	Input Files	Output Files	Comments
SETPNS	--	PNSERT.DAT (Random Access) (DK)	Put transform of 3 repetitions of PN sequence in file PNSEQT.DAT.
SETLAG	--	LAGR.DAT (DK) LAGD.DAT (DK)	Lagrange interpolation coefficients LAGR.DAT → order 2 LAGD.DAT → order 4
HFSIMS	--	HFSIMS.DAT (DK)	Put transform of channel snapshots in HFSIMS.DAT.
PLYSCF	LAGR.DAT (DK) PNSEQT.DAT (Random Access) (DK) HFSIMS.DAT (MT)	TESTD.DAT (DK)	Create test channel (TESTD.DAT) by playing PN sequence through channel snapshots created by HF simulator
RECSCF	LAGR.DAT (DK) TESTD.DAT (DK)	STOR1.DAT (DK) NAME.DAT (MT)	TEST.DAT contains baseband signal. Program prefilters, creates complex channel, correlates, and interpolates with Lagrange interpolator of order 2. Records of NAME.DAT=255.
CHFFT	NAME.DAT (DK)	FFT255.DAT (DK)	Read in record M of NAME.DAT FFT and put in file FFT255.DAT.
PLOTCH	FFT255.DAT (DK)	--	Plots.
DDSPEC	NAME.DAT (MT)	DELDOP.DAT (DK)	Compute delay Doppler spectrum.

even at the lowest Doppler resolution increment (0.551 Hz), we chose to perform the first test over 40 seconds of data. As a first-order estimate, this implies that spectral averaging will include at least 22 independent samples. Therefore, we can expect the standard deviation of any statistical results to be 21.3% of the actual value.

User input to HFSIMS included: 1) CHANL as the name of the output data file (.DAT assumed); 2) 1410 (40 second) snapshots to be processed; 3) 128 frequency samples in the upper sideband (including one sample at the lower band-upper band transition point); 4) a 35.294-Hz snapshot rate; and 5) a separation between frequency samples of 35.294 Hz. Data specified for a two-path test is presented in Table 3-2.

After executing HFSIMS, FLYSCF, and RECSCF, the reconstructed synthetic channel snapshots are written in file CHANL.DAT. As an intermediate check on software execution, programs CHFFT (Figure A.32) and PLOTCH (Figure A.33) plot the magnitude in dB of an FFT of any desired record in CHANL.DAT. NRL's Versatec matrix plotter software is required for PLOTCH. A plot of the 14th such record appears in Figure 3.9. Although the exact features of the two-path model are not easily discerned because they have been all but obliterated by the effects of Doppler, some important observations can be made. On the frequency normalized to sampling rate scale, the upper sideband falls in the region 0.0 to 0.5. Notice the small amount of energy in the lower sideband. Both sidebands were prefiltered in RECSCF with a raised cosine weighting. The nulls of this weighting at normalized frequencies 0. and .5 are obvious. In addition, the raised cosine weighting is apparent in the mainlobe of the upper sideband.

TABLE 3-2
TWO-PATH TEST DATA SUMMARY

Parameter	Path 1	Path 2
Doppler Standard Deviation (Hz) (RMS Doppler Spread)	0.5 (1.0)	1.5 (3.0)
Doppler Shift (Hz)	1.5	-1.5
Path Delay (sec)	0	0.0005

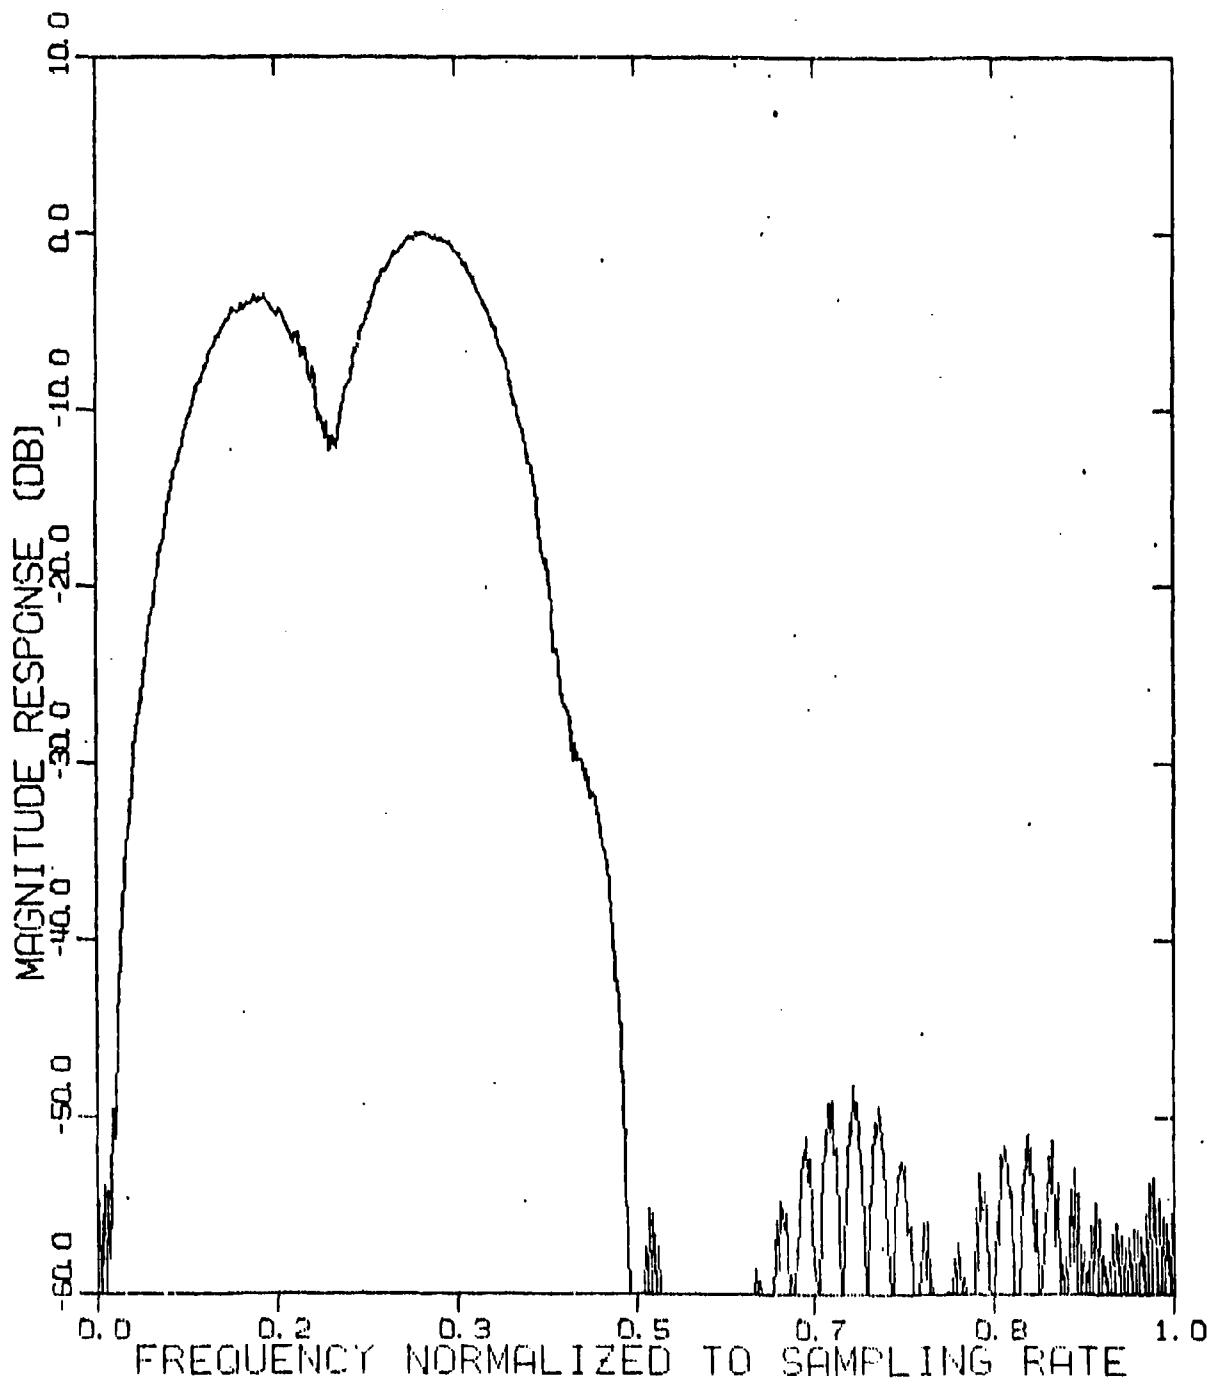

Figure 3.9 FFT Magnitude of 14th Snapshot of RECSCF Output
(Two-Path Model with Doppler)

In order to more graphically illustrate the influence of a two-path model on spectral particulars, we performed a separate test in which neither path was subject to any Doppler effects. The results of plotting the spectrum of the 14th record of CHANL.DAT appears in Figure 3.10. The characteristics to which we referred in the previous paragraph are vividly portrayed.

DDSPEC completes the basic software processing. In addition to the name of the input data file, it requires the indices of the left and right tap boundaries of the taps to be examined. This can be obtained from RECSCF's printout of power at each tap location summed over all snapshots. The data for this test is reproduced in Figure 3.11. Observe that nearly all delay power falls between taps 20 and 33. After running DDSPEC, DDREAD should be executed (if necessary, several times until all the taps processed are examined). Because of space, its output is given in two parts. Figure 3.12(a) contains Dopplers from -17.647 Hz to -0.551 Hz; Figure 3.12(b) contains Dopplers from 0 Hz to 17.096 Hz. The peaks of the delay Doppler lobes for each path are underlined. Observe that they are separated by 4-1/2 taps (0.0005 second). The user can get a feeling for spread in the Doppler dimension by comparing the ratio of Doppler power densities at two similar points for each path. In this manner, it is easy to see that the second path has a much broader Doppler bandwidth than the first path. However, the peak of the second path is smaller than that of the first because the integrated power density for the two paths was user-specified to be equal.

A statistical summary of the data in Figure 3.12 is given by the output of DDSTAT in Figure 3.13. Observe that the claims for delay peak and Doppler peak locations are proportional to some multiple of an index of delay or Doppler increments. For example,

DOPPLER STATISTICS FOR THE 14 TAPS EXAMINED:

	DOPPLER MEAN (HZ)	RMS DOPPLER SPREAD (HZ)	RELATIVE TAP ENERGY (dB)
TAP 1	-2.212	10.500	-47.681
TAP 2	1.479	1.284	-15.410
TAP 3	1.489	1.282	-6.017
TAP 4	1.481	1.280	-1.423
TAP 5	1.481	1.283	0.020
TAP 6	1.459	1.359	-1.397
TAP 7	0.339	2.972	-4.857
TAP 8	-1.141	5.241	-4.355
TAP 9	-1.387	2.931	-1.862
TAP 10	-1.386	2.931	-1.863
TAP 11	-1.385	2.922	-4.787
TAP 12	-1.377	2.908	-11.407
TAP 13	-1.369	2.933	-25.683
TAP 14	-1.255	5.190	-33.397

Figure 3.13 (Continued)

a Doppler peak at -1.654 Hz corresponds to three times the Doppler step size of 0.551 Hz, while the actual Doppler peak is at -1.5 Hz. More accurate peak location by numerical interpolation can be included if the need arises for more than just gross channel parameters.

Of particular interest in Figure 3.13 are the Doppler statistics for the 14 taps examined. According to Table 3-2, the channel path at 0 relative delay should have an rms Doppler spread of 1 Hz, while the path at 0.5 msec relative delay should have an rms Doppler spread of 3.0 Hz. Noting from the printout that delay peaks occur at taps 5 and 9, we can easily verify that the measured rms Doppler spreads for the two-paths are 1.28 Hz and 2.93 Hz, respectively. These numbers seem reasonable in view of the previously discussed 21% standard deviation in measurement.

As a visual aid to the user, DDSTAT plots marginal delay power and marginal Doppler power. These appear in Figures 3.14 and 3.15, respectively. Observe that the 0.5-msec path separation is easily resolved by the programs. The 3-Hz Doppler shift between paths is also easily resolved. In fact, it seems reasonable that, for small Doppler spreads, less than 1-Hz resolution should be possible for Doppler peaks at the same delay.

In an effort to more clearly demonstrate the resolution capabilities of the software processor, we have conducted a second test with each channel path less distinct from the others in delay and Doppler than the channel paths in the first test. A summary of the delay and Doppler characteristics for this three-path test case is presented in Table 3-3. The relative path delays specified are chosen to place peaks in the measured delay power spectrum at integral multiplies of the intertap spacing in seconds. This allows best-case estimation of software delay resolution capabilities. Observe that the intertap spacings correspond to 2 and 3 taps, respectively — in distinction to the first test in which the path delay was equivalent to 4-1/2 taps.

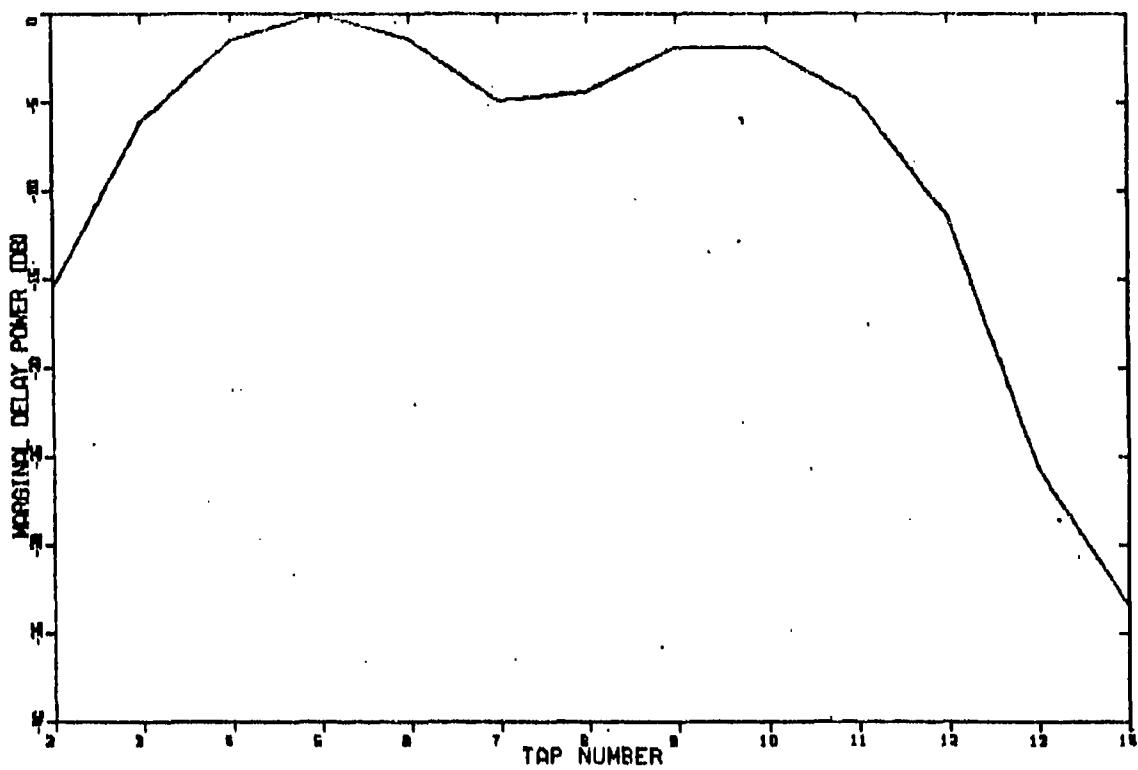

Figure 3.14 Marginal Delay Power in dB for First Test Example
(Each tap separated by 0.111 msec)

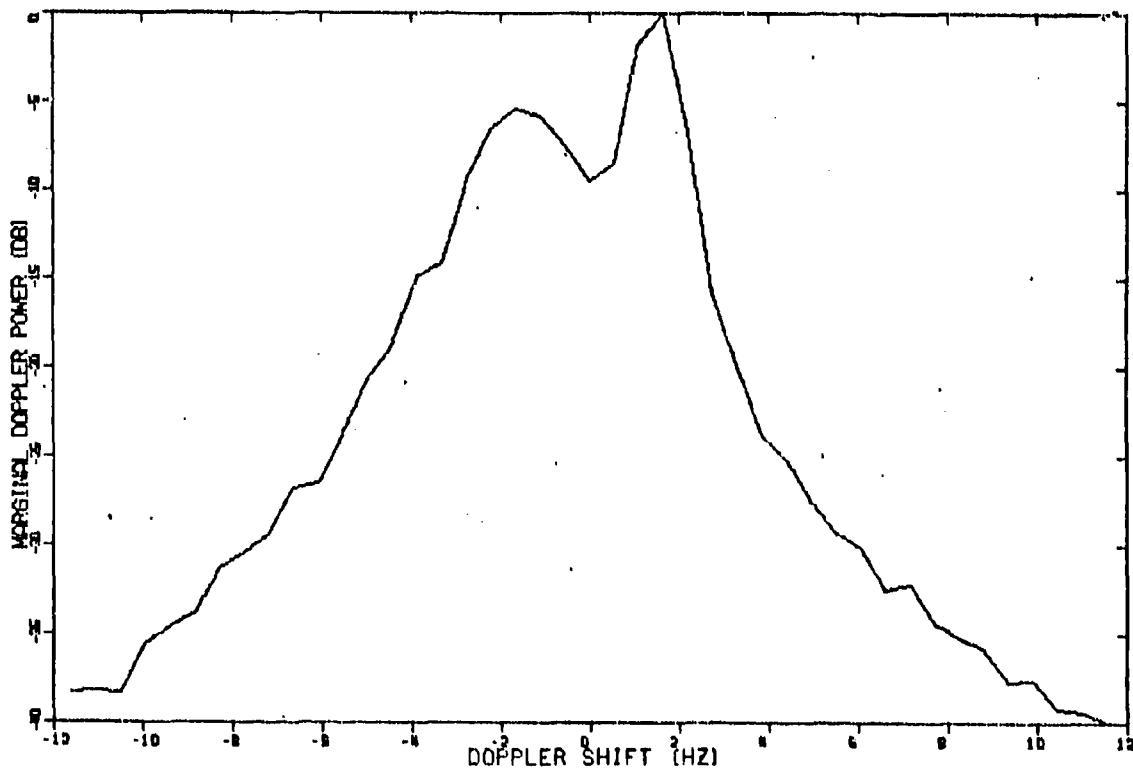

Figure 3.15 Marginal Doppler Power for First Test Example

TABLE 3-3
THREE-PATH TEST DATA SUMMARY

Parameter	Path 1	Path 2	Path 3
Doppler Standard Deviation (Hz) (RMS Doppler Spread)	0.25 (0.5)	0.25 (0.5)	0.25 (0.5)
Power (dB)	-4.771	-4.771	-4.771
Doppler Shift (Hz)	-1.102	-1.653	-2.755
Path Delay (sec)	0	0.000222	0.000555

Doppler shift magnitudes are constrained to be (1) less than 3 Hz in order to minimize deterioration resulting from interpolation filters in RECSCF and PLYSCF, and (2) greater than 1 Hz in order that spectral estimates be averaged over as large a number of independent samples as possible. Since the test has been conducted over 60 seconds of data, even at 0.55 Hz we can expect a standard deviation in measurement of 17%. In addition, the mean of each Doppler lobe is placed at an integer multiple of resolution cell increments (0.551 Hz). The rms Doppler spread of each path is less than one resolution cell.

As noted previously, RECSCF (in addition to its function of measuring the complex channel snapshots) also outputs the average tap power for the entire processing time. This information is reproduced in Figure 3.16. The two measured peaks are underlined. Without resolution limitations, the three-path peaks would have appeared at the 24th, 26th, and 29th tap. It is clear that the peak which occurs at the 25th tap is a result of the first and second paths combining.

The results of running DDSPEC and DDREAD appear in Figures 3.17(a) and 3.17(b). As before, delay Doppler peaks are underlined. It is relatively easy to determine peaks in the two-dimensional delay Doppler surface before marginal distributions are derived. However, the user must resort to first derivative estimation in order to distinguish the first two paths.

The statistical information obtained with the aid of DDSTAT is presented in Figure 3.18. As expected, the program finds only two peaks in delay and Doppler. It should be remembered, however, that the number of peaks in the marginal distributions is not necessarily the same as the number of distinguishable peaks in the delay Doppler surface.

Figure 3.18 (Continued)

The Doppler statistics for the 14 taps examined merit some comment. The measured Doppler shifts at taps 4, 6, and 10 of -1.13 Hz, -1.4 Hz, and -2.71 Hz, respectively, agrees well with the specified values of -1.1 Hz, -1.65 Hz, and -2.76 Hz, especially considering the measurement corruption resulting from path interference. However, the measured Doppler spread at each of these taps is approximately twice the value which had been expected. This is a result of the mainlobe width of the window function used for spectral estimation. This can be reduced by increasing the length of the window (and the associated FFT); however, for a fixed duration data sample, this would reduce the number of periodograms over which averaging is performed and increase the variance of the estimate.

Graphical presentation of marginal delay power and marginal Doppler power appears in Figures 3.19 and 3.20, respectively. Coalescence of the first two paths in both delay and Doppler is obvious. However, the position of the third path, which is separated from the others by a minimum of three taps and 1.1 Hz, is easily extracted. We might estimate the lower resolution of the present software system to be $\frac{1}{3}$ msec in delay and 1 Hz in Doppler.

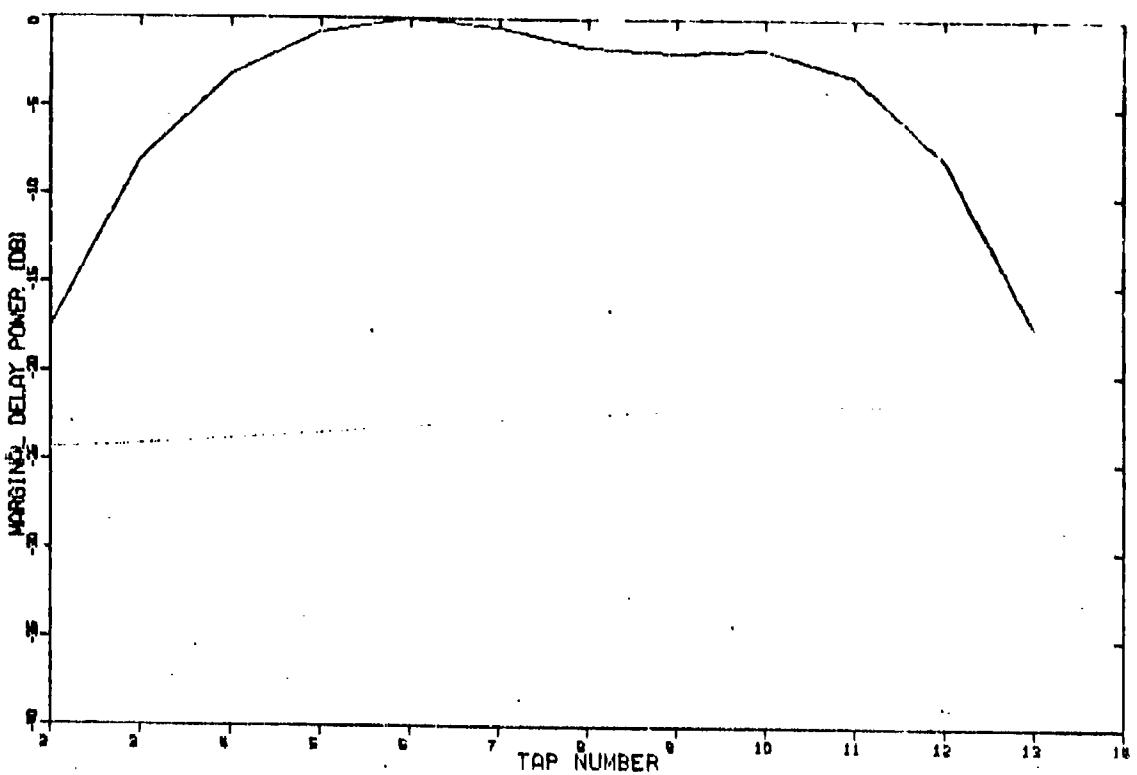

Figure 3.19 Marginal Delay Power (Second Test Example)

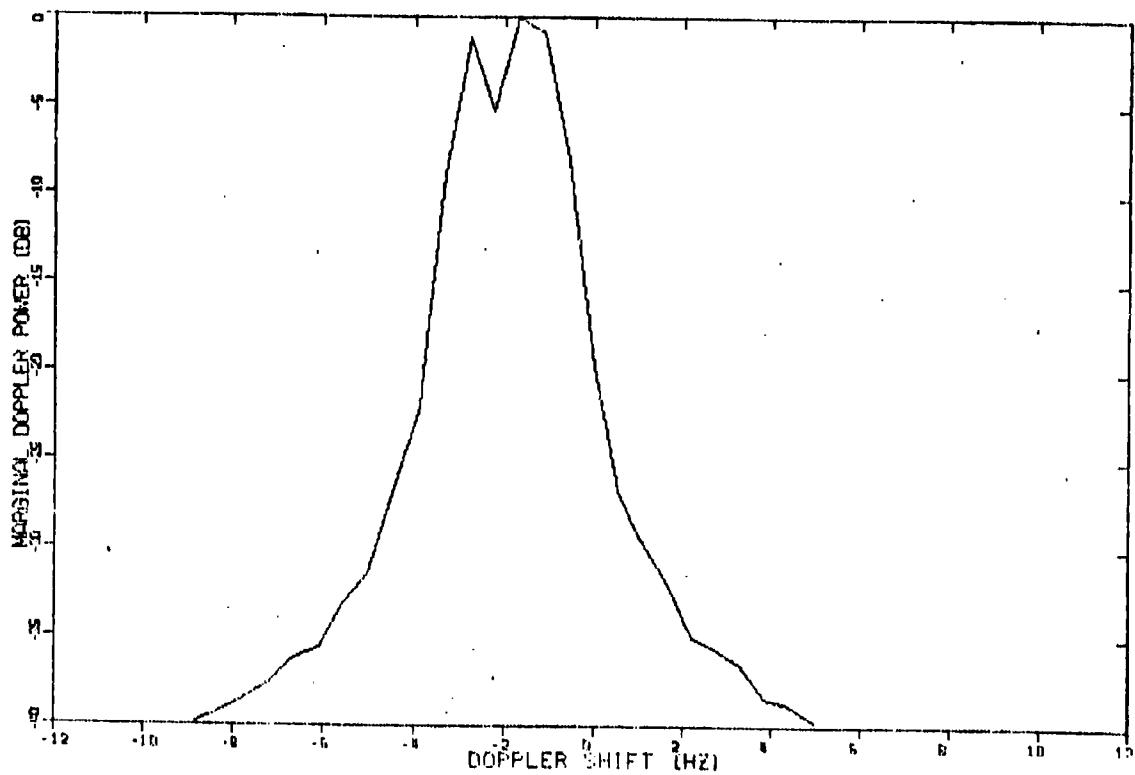

Figure 3.20 Marginal Doppler Power (Second Test Example)

18. ABSTRACT (Continue on reverse side if necessary and identify by block number) The process of probing and measuring an HF channel for use in a stored channel simulator will prove useful only when the investigator has some knowledge of the channel conditions. Of particular interest are the channel Doppler characteristics and multipath structure. The operations required to provide a measure of these parameters include: (1) complex channel

reconstruction; (2) prefiltering to improve delay resolution; (3) channel snapshot generation; and (4) Doppler estimation. A set of flexible Fortran programs which meet these specifications are described in detail. Software verification is achieved by means of a program generated single sideband HF test channel. In addition, programming changes to the previously reported channel measurement and reproduction software are documented. These result in significant decreases in computation time.
